1 SM and beyond: Allowed, forbidden and discovery processes

All Feynman graphs are shown below, and the type of reaction(s) is specified behind each process. The particle decays present here are those of the anti-tau lepton (graph 5), two different Higgs decays (graphs 12 and 17), and of the upsilon meson. the lifetime of a particle can be estimated from the vertex factors present in the Feynman diagram. This can be seen from Fermi's golden rule:

$$\Gamma_{fi} = 2\pi |T_{fi}|^2 \rho(E_i) \quad (1)$$

where Γ_{fi} is the transition rate between states i and f , T_{ij} is the transition matrix element¹ ($\langle f | H' | i \rangle$, where H' is a perturbation causing a change of state), and $\rho(E_i)$ is the state density. The T-matrix is proportional to \mathcal{M} , the scattering probability matrix for two states, and often the root of problems in particle physics. This matrix is equal to the sum of proportioned products of vertex factors² So, for a certain decay process, one considers a certain "path" of decay only. Therefore, the transition rate (or decay rate, in the case of decays) is proportional to the product of vertex factors. Although certainly not applicable to verify any theories, the estimate of the decay rate gives a rough idea of both the branching ratio of a certain decay and the lifetime of that particle.

1.1 Lifetimes and branching ratios

1.1.1 $\tau^+ \rightarrow \mu^+ \nu_e \bar{\nu}_\tau$

In process 5, a anti-tau-lepton decays by emitting a W^- -boson. As the mass difference between a tau lepton and muon is about the same as that between a muon and electron (negligible mass in comparison), one can use the formula for the decay rate of the muon³:

$$\Gamma_\mu = \left(\frac{m_\mu g_w}{M_W} \right)^4 \frac{m_\mu c^2}{12\hbar(8\pi)^3} \quad (2)$$

for the decay rate of the tau lepton, but recall the tau lepton can decay both an electron and muon (leptonically), whereas muon only to an electron. Since the only difference is now the mass, one can relate the lifetimes:

$$\frac{\tau(\tau \rightarrow \text{leptons})}{\tau(\mu \rightarrow \text{leptons})} = \frac{m_\mu^5}{2m_\tau^5} \longrightarrow \tau_\tau = \frac{1}{2} \left(\frac{m_\mu}{m_\tau} \right)^5 \tau_\mu \quad (3)$$

where the factor of 2 is due to τ having twice as many decay modes. Inserting experimentally found values for m_μ , m_τ and τ_μ , one finds:

$$\tau_\tau \simeq 8.16 \times 10^{-13} \text{ s} \quad (4)$$

The full decay width is given by $\Gamma_{\text{tot}} = 1/\tau$, meaning the branching ratio is:

$$\frac{\Gamma_{\tau^+ \rightarrow \mu^+ \nu_e \bar{\nu}_\tau}}{\Gamma_{\text{tot}}} \simeq \tau_\tau \left(\frac{m_\tau g_w}{M_W} \right)^4 \frac{m_\tau c^2}{12\hbar(8\pi)^3} \quad (5)$$

¹Or simply the "T-matrix, as its often called.

²This is a bit of a mouthful. Essentially, $\mathcal{M}_{if} = \sum_j a_j \prod_{k_j} V_{k_j}$, where the sum runs over all processes going from i to j , and the product symbol runs over all interaction vertices for that specific process. With the standard model in place, the vertices are easily read off the Feynman diagrams, but the problems remain in; 1) finding the a_j -terms and 2) considering enough diagrams to get sufficient accuracy.

1.2 Suppression and forbidding of processes

All the processes are fine when considering conservation numbers (with the possible exception of 5, explained below) such as family numbers, charge and spin. However, there are some processes that are unfavourable due to other phenomenon.

In process 5, it is suggested a anti-electron neutrino is created. This would violate lepton family number conservation, which is normally conserved, with the exception of neutrino oscillations. While it is a bit odd, the reaction is allowed, after some time. Momentarily after the reaction, however, there would have had to be a anti-muon neutrino, should the theoretical model be correct.

Process 9 shows double Higgs production in an electron-positron annihilation. This brings about a problem due to the enormous difference in initial and final mass. So far, one has not been able to accelerate these leptons to such velocities, because of the curved accelerators in use today. With the promise of linear accelerators in the close future, reactions such as these may be a reality. However, theoretically these reactions can happen, given enough energy. This problem also holds for process 11, 12, and 20.

1.3 Important processes

Process 3: Should one ever measure this process, it would mean the existence of supersymmetry, a theory that explains many of the mysterious free parameters in the standard model.

Process 4: Unsure.

Process 8: Unsure.

Process 10: This process is of interest as it proves the quark changes type by the W -bosons, due to W having charge, and becomes an anti-particle by a Z_0 -boson, since it's neutral.

Process 11: Electron-positron annihilation provide important data on weak interactions. this reaction would provide 3 beams originating from each Z -boson, providing information on each.

Process 14: This process proves the $ZZHH$ vertex, one of the predictions of the electroweak model.

Process 18: The J/Ψ meson has a very narrow decay width, meaning it's very well measurable. This means it can be used for the calibration of detectors.

2 Top quark and W-boson

2.1 The CKM matrix and the function of the W-boson

The Cabibbo-Kobayashi-Maskawa (CKM) matrix is defined as:

$$\begin{bmatrix} d' \\ s' \\ b' \end{bmatrix} = \begin{bmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{bmatrix} \begin{bmatrix} d \\ s \\ b \end{bmatrix} \quad (6)$$

The right quark states are mass-eigenstates, meaning they are written a basis which diagonalizes the mass-matrix term in the Lagrangian density function. The left, Cabbibo-rotated, quark states are what couple to up-type quarks. The matrix is given by the equation:

$$V = U_u^\dagger U_d \quad (7)$$

where U_u and U_d are the necessary rotations of the quark triplets (u,c,t) and (d,s,b) such that the mass matrices in the Lagrangian are diagonalized:

$$u_L^i \rightarrow U_u^{ij} u_L^j, \quad d_L^i \rightarrow U_d^{ij} d_L^j \quad (8)$$

It is interesting to note that the CKM matrix, from its definition is believed to be unitary, which, so far, fits quite well with experimental results. In other words, in theory the entire matrix could be found be knowing only a bit more than half the terms. In the weak interaction, quark flavour can interchange by transition between up and down type quarks. This interchange is only permissible due to the W-boson. Theoretically, the W-boson links three u_L^i fermion fields (quarks)⁴ to the down type triplet. This can be seen from the equation:

$$J^{\mu+} = \frac{1}{\sqrt{2}} \bar{u}_L^i \gamma^\mu d_L^i \rightarrow \frac{1}{\sqrt{2}} \bar{u}_L^i \gamma^\mu (U_u^\dagger U_d)^{ij} d_L^j = \frac{1}{\sqrt{2}} \bar{u}_L^i \gamma^\mu V^{ij} d_L^j \quad (9)$$

while quite out of context, this expression shows the transformation properties, under the rotation of mass eigenstates, of the terms in the Lagrangian that couple to the W-boson, where $J^{\mu+}$ (called the W-boson current) is the "coefficient" of the W-boson gauge field in the Lagrangian. As one sees, the W-boson only couples to one up-type and one down-type quark, meaning it's necessary for flavour changes in the weak interaction.

The elements of the CKM matrix can be determined experimentally, as the absolute squares of the elements are included in the coupling coefficients, and thus proportional to the branching ratio, which can be determined experimentally. Three of the elements have been determined using the following decays:

- Superalowed β -decay.
 - $K^+ \rightarrow \pi^0 e^+ \nu_e$
 - $B^0 \rightarrow \pi^- e^+ \nu_e$

How one can determine the matrix elements due to experimental data is because of the relation:

$$W_{i \rightarrow j} = \frac{BR(i \rightarrow j)}{\tau} \propto |V_{ij}|^2 \quad (10)$$

So by measuring the branching ratio of some decay, one can, by also knowing the decaying particle's average lifetime and the proportionality constant (determined theoretically or as form factors), solve for the absolute square of the matrix element.

⁴Here L symbolizes the quarks being left-handed (doublets in $SU(2)$ representation), while the index i is for each up quark flavour (u,c,t).

2.2 Top quark production

There are 3 processes that are commonly used for top quark production: e^-e^+ , pp and $p\bar{p}$.

Electron-positron annihilation creates an intermediate photon or Z-boson that both can decay into a l^-l^+ state or $q\bar{q}$ state. Therefore, the process $e^-e^+ \rightarrow t\bar{t}$ is fully possible, if not a bit unfavourable.

In a pp collision there are no annihilations, only high energy collisions. In these collisions, gluons are emitted from one or several of the quarks in one or both of the protons. It is therefore fairly straight forward to realise any one of these gluons can produce a top-anti-top product.

The final process, $p\bar{p}$, a quark and an anti-quark (either up or down) can annihilate to make a gluon which again makes a top-anti-top product.

The only two observed processes that produce a single top quark are:

- $W^+ \rightarrow t\bar{b}$
- $b \rightarrow W^-t$

The production of a W^+ -boson can happen in a great number of ways for the process above, as any up-type quark can change type by emitting such a boson. The same can be said for a bottom quark, as a gluon can also decay into bottom-anti-bottom, either of which can decay into a top-flavour quark.

See the diagrams for the lowest order contributing diagrams for both single and pair top production.

2.3 Top quark decay

The top quark decays by transforming into either a b, s or d quark, while emitting a W-boson. Of the three, it is far more likely to decay to a bottom quark, with a branching ratio of about 0.91. Considering this, it can decay in a limited number of ways, all of which are dependant on what the emitted W-boson decays into afterwards. Many usually just write the top-decay as $t \rightarrow W^+b$, without filling in the decay products of W^+ .

Experimentally⁵, the top quark can be identified by 4 different measurable outcomes. Since the top

Example event displays of the first top quark pair production candidates observed at the LHC. Left: A di-lepton candidate observed in ATLAS~\protect\cite{ATLAS-CONF-2010-063}. Right: A lepton+jets candidate observed in CMS~\protect\cite{CMS-PAS-TOP-10-004}.

quark is prone to decay into a b-quark, it will emit a W -boson. In every case, the b-quark will hadronize and form a jet. What remains is how the W -boson decays:

1. A quark pair production, giving two jets.
2. A τ -lepton, which can decay into either other leptons or hadrons, which means it is hard to distinguish from other particle productions.
3. An electron or muon (and a neutrino). As these particles are quite stable and charged, they will be measured directly.

Lastly, in the case of top-pair production, the combination of W decays will be measured. For example, should each W -boson decay hadronically (all hadronic channel), 6 jets will form (4 from quark pairs, 2 from bottom quarks). Both the bosons could also decay leptonically (dileptonic channel), giving 2 jets and 2 leptons. The last measurable outcome is if one decays leptonically and the other hadronically, giving 4 jets and 1 lepton.

The top quark is special in a few ways. First, and most important of all, is its short lifetime; 10^{-25} s. As the top quark decays long before hadronizing could happen, the decay product provide a means to measure a solitary quark. Another point is that it was the last quark (to complete the standard model) to be found, proving quarks had the same group properties of the leptons (3 families, 2 types), and that quarks also fit into weak interaction theory.

In the Atlas overview (left side), one can see one candidate for top-pair production. There are two jets, blue and red, and two leptons deviating a bit from each jet, green and yellow. This fits nicely, as the apparent total momentum of each of these products appear to zero. Since there are two jets (bottom quarks) and two leptons (W -boson decay), this is a dileptonic decay.

2.4 Branching ratios of two top quark decays

The two top quark decays $t \rightarrow b + c\bar{s}$ and $t \rightarrow b + \tau + \nu_\tau$ occur by emission of a W -boson. The decay rate can be calculate in terms of the muon decay rate⁶, thanks to Sargent's law and the huge mass difference in initial and final states, through the relation:

$$\Gamma_{p_i} = \prod_j V_j \frac{m_t^5}{m_\mu^5} \Gamma_\mu \quad (11)$$

⁶Which is fine, as this is one of the best known decays.

where V_j are the vertex factors of decay mode i . To give a clearer idea as to what this means, one can estimate the decay rates of the two decays of interest:

$$\Gamma_1 = 3|V_{tb}|^2|V_{cs}|^2\Gamma_0 \quad (12)$$

$$\Gamma_2 = |V_{tb}|^2\Gamma_0 \quad (13)$$

$$(14)$$

where $\Gamma_0 \equiv \frac{m_t^5}{m_\mu^5}\Gamma_\mu$. The factor of 3 is due to colour charges available to the $c\bar{s}$ -pair⁷. The full decay width is:

$$\Gamma_{\text{tot}} = 3|V_{tb}|^2 [1 + (|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 + |V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2)] \Gamma_0 \quad (15)$$

$$\simeq 3|V_{tb}|^2 \times 3 \times \Gamma_0 \quad (16)$$

$$= 9|V_{tb}|^2\Gamma_0 \quad (17)$$

i.e. the sum over all possible decay modes for the W^+ -boson, times the initial top decay. Therefore, the branching ratios are roughly:

$$\frac{\Gamma_1}{\Gamma_{\text{tot}}} \simeq \frac{3|V_{tb}|^2|V_{cs}|^2\Gamma_0}{9|V_{tb}|^2\Gamma_0} = \frac{0.97344|^2}{3} \simeq 0.3158$$

$$\frac{\Gamma_2}{\Gamma_{\text{tot}}} \simeq \frac{|V_{tb}|^2\Gamma_0}{9|V_{tb}|^2\Gamma_0} = \frac{1}{9} \simeq 0.1111 \dots$$

So, the quark decay is about 3 times more prone to occur than the leptonic decay.

3 Gauge theories

3.1 Symmetries and conservation laws of the standard model

The standard model contains, among several, all the symmetries presented by the following direct product of groups:

$$SU(3) \times SU(2) \times U(1) \quad (18)$$

The product $SU(2) \times U(1)$ describes the electroweak theory; the unification of quantum electrodynamics (QED) and weak interaction (WI) theory (GWS theory⁸). It is also common to write $SU(2)_L$ to remind that the gauge fields of this group only couple to left-handed fermion fields.

Starting with the simplest, the symmetry group $U(1)$ is used in QED as one claims a local symmetry under unitary rotations of fermion fields (phase transform), i.e. the Lagrangian is invariant under:

$$\psi \rightarrow e^{i\theta(x)}\psi \quad (19)$$

In order for this to hold, the covariant derivative must be introduced: $\bar{\psi}\not{\partial}\psi \rightarrow \bar{\psi}\not{D}\psi$. The covariant derivative (D) introduces a massless gauge field (usually denoted A_μ), which behaves just like the photon as a force mediator.

The WI symmetry group has 3 generators (degrees of freedom for $SU(n) : n^2 - 1$), which means there are 3 gauge bosons present in the covariant derivative. These gauge bosons can be used to make W^\pm and

⁷This is not the case for the top-transform to a b -quark, as the top already has a specific colour.

⁸Sheldon Glashow, Abdus Salam and Steven Weinberg.

W^0 . Only with electroweak theory will one get Z_0 . Invariance under $SU(2)_L$, where L means the gauge fields only couple to left-handed fermion fields, can, in electroweak theory, be shown to conserve the weak isospin.

The QCD symmetry group has 8 generators (giving 8 gauge fields), which gives rise to 8 intermediate vector bosons (the gluons). In much the same manner as for WI, it can shown colour charge is conserved.

3.2 The gauge principle and deriving the QCD Lagrangian

The gauge principle is a procedure for finding how particles interact under certain continuous symmetries, which in the case of the standard model are under $SU(3)$, $SU(2)$ and $U(1)$ ⁹. By starting with the free field Lagrangian, it is demanded the Dirac field is invariant under some local¹⁰ symmetry transformation. In order to fulfil such a demand, certain changes to the Lagrangian must be done (making a covariant derivative), which is the where the exchange bosons come into play.

The $SU(3)$ symmetry group and it's role in the standard model came about not long after the propositions of the "eightfold way", to categorize baryons according to their quantum numbers, and quark flavour to explain the these numbers (isospin,).

However, this did not explain the existence of the Ω^- hyperon, which seemed to violate the Pauli exclusion principle due to its constituents all, apparently, existing in the same state. Therefore, the colour charge was proposed; each baryons' quarks had a different colour charge, so there were 3 possible "colours". This is why the irreducible representation of $SU(3)$ fits nicely in with its three degrees of freedom and where quantum chromodynamics has its birth.

Deriving the QCD Lagrangian by the gauge principle is done as follows; starting with the free Lagrangian

$$\mathcal{L}_{free} = \sum_f \bar{q}_f (i\partial - m_f) q_f \quad (20)$$

where q_f is a Dirac spinor for flavour type f , a $SU(3)$ field transformation is performed:

$$q_f^\alpha \rightarrow U_\beta^\alpha q_f^\beta \quad (21)$$

where $U = e^{-ig_s \frac{\lambda^a}{2} \theta_a}$ and λ^a are the Gellmann matrices in the fundamental representation. As is standard, now locality is demanded: $\theta_a \rightarrow \theta_a(x)$. Of course, the problem now is that the Lagrangian is not invariant under such a transform, so a covariant derivative must be found.

In non-abelian gauge theory, for local invariance under some symmetry (Lie) group ($\psi \rightarrow V(x)\psi$), The unitary matrix $V(x)$ can be expanded infinitesimally about x :

$$V(x) = 1 + i\alpha^i(x)t^a + \mathcal{O}(\alpha^2) \quad (22)$$

where t^a are the generators of the group and α^i some rotation. From the definition of the covariant derivative along a vector n^μ :

$$n^\mu D_\mu \psi = \lim_{\epsilon \rightarrow 0} \frac{1}{\epsilon} [\psi(x + \epsilon x) - U(x + \epsilon x, x)\psi(x)] \quad (23)$$

where

$$U(y, x) \rightarrow V(y)U(y, x)V^\dagger(x) \quad (24)$$

So by infinitesimal expansion, in the case of $SU(3)$ ($V(x) = e^{-ig_s \frac{\lambda^a}{2} \theta_a(x)}$):

$$U(x + \epsilon, x) = 1 + ig_s \epsilon n^\mu G_\mu^a \lambda_a + \mathcal{O}(\epsilon^2) \quad (25)$$

⁹There are other symmetries in the Standard model, but none that provide insight to interactions, e.g. Lorentz invariance.

¹⁰By locality, one means a continuous transform under the symmetry group at some space-time point.

Here G_μ^a are the gauge fields of $SU(3)$, later to be identified with the gluon fields. The absence of θ , from V , is due to the details of the expansion. When inserting the above in equation 23 and taking the limit, it follows:

$$D^\mu q_f = \left[\partial^\mu - ig_s \frac{\lambda^a}{2} G_\mu^a(x) \right] q_f \quad (26)$$

In order for this to transform in the same manner as the quark field alone,

Thus the first order interactive term between the quarks and gluons is found, but the gauge-invariant kinetic gluon term remains hidden. Again, from non-abelian gauge theory it is known that the field strength must be found.

The covariant derivative transforms as:

$$D^\mu \rightarrow U D^\mu U^\dagger \quad (27)$$

This is known because $D^\mu q_f$ is invariant, and since U is unitary: $D^\mu q_f \rightarrow U D^\mu q_f U^\dagger = U D^\mu U^\dagger U q_f U^\dagger$. So the above transform means the gluon field transforms as:

$$G^\mu \rightarrow U G^\mu U^\dagger - \frac{i}{g_s} (\partial^\mu U) U^\dagger \quad (28)$$

This is obviously not an invariant quantity then. Instead, one can introduce a tensor:

$$\begin{aligned} G^{\mu\nu}(x) &\equiv \frac{i}{g_s} [D^\mu, D^\nu] \\ &= \partial^\mu G^\nu - \partial^\nu G^\mu - ig_s [G^\mu, G^\nu] \\ &\equiv \frac{\lambda^a}{2} G_a^{\mu\nu}(x) \end{aligned}$$

where:

$$G_a^{\mu\nu} = \partial^\mu G_a^\nu - \partial^\nu G_a^\mu + g_s f^{abc} G_b^\nu G_c^\mu \quad (29)$$

and f^{abc} is the group structure constant. Now one has an invariant term:

$$G^{\mu\nu} \rightarrow U G^{\mu\nu} U^\dagger \quad (30)$$

In order to get kinetic terms, and to remove the free indices, the final Lagrangian is:

$$\mathcal{L}_{\text{QCD}} = -\frac{1}{4} G_a^{\mu\nu} G_{\mu\nu}^a + \sum_f \bar{q}_f (i\gamma^\mu D_\mu - m_f) q_f \quad (31)$$

Just in appearance, this is identical to the QED Lagrangian. However, there are important differences. The biggest difference between the QED and QCD Lagrangian lies of course in the "force carriers", where there is one photon and eight gluons. This means that whereas there are no photon-photon couplings, there are gluon-gluon couplings. Additionally, the electric charge in the QED Lagrangian is unique for each fermion. In QCD, the colour charge is the same for all fermions. This is tied to QED employing $U(1)$, i.e. the transformation of each fermion was linear such that the "coefficients" are free to be chosen. In $SU(3)$, however, the transformations are non-linear (λ_a and λ_b determine λ_c). As such, g_s is the same for all fermions; the strong coupling constant.
